Instructor: Engr. Robin Valenzuela	Semester and SY: First 2024-2025
Activity F. Consolidating Playbook plays	

Activity 5: Consolidating Playbook plays

1. Objectives:

- 1.1 Use when command in playbook for different OS distributions
- 1.2 Apply refactoring techniques in cleaning up the playbook codes

2. Discussion:

We are going to look at a way that we can differentiate a playbook by a host in terms of which distribution the host is running. It's very common in most Linux shops to run multiple distributions, for example, Ubuntu shop or Debian shop and you need a different distribution for a one off-case or perhaps you want to run plays only on certain distributions.

It is a best practice in ansible when you are working in a collaborative environment to use the command git pull. git pull is a Git command used to update the local version of a repository from a remote. By default, git pull does two things. Updates the current local working branch (currently checked out branch) and updates the remote-tracking branches for all other branches. git pull essentially pulls down any changes that may have happened since the last time you worked on the repository.

Requirement:

In this activity, you will need to create a CentOS VM. Likewise, you need to activate the second adapter to a host-only adapter after the installations. Take note of the IP address of the CentOS VM. Make sure to use the command *ssh-copy-id* to copy the public key to CentOS. Verify if you can successfully SSH to CentOS VM.

Task 1: Use when command for different distributions

- 1. In the local machine, make sure you are in the local repository directory (CPE232_yourname). Issue the command git pull. When prompted, enter the correct passphrase or password. Describe what happened when you issue this command. Did something happen? Why?
- 2. Edit the inventory file and add the IP address of the Centos VM. Issue the command we used to execute the playbook (the one we used in the last activity): ansible-playbook --ask-become-pass install_apache.yml. After executing this command, you may notice that it did not become successful in

the Centos VM. You can see that the Centos VM has failed=1. Only the two remote servers have been changed. The reason is that Centos VM does not support "apt" as the package manager. The default package manager for Centos is "yum."

```

192.168.56.103 : ok=4 changed=1
ed=0 skipped=0 rescued=0 ignored=0
                                               unreachable=0
                                               unreachable=0
                                                                 fail
                        : ok=1 changed=0
                                                unreachable=0
 Show Applications © rescued=0 ignored=0
```

3. Edit the *install apache.yml* file and insert the lines shown below.

```
    hosts: all become: true tasks:
    name: update repository index apt:
        update_cache: yes when: ansible_distribution == "Ubuntu"
    name: install apache2 package apt:
        name: apache2 when: ansible_distribution == "Ubuntu"
    name: add PHP support for apache apt:
        name: libapache2-mod-php when: ansible_distribution == "Ubuntu"
```

Make sure to save the file and exit.

```
File Edit View Search Terminal Help
                            install_apache.yml
 GNU nano 2.9.3
- hosts: all
 become: true
 tasks:
 - name: install apache2 package
   apt:
     name: apache2
   when: ansible_distribution == "Ubuntu"
 - name: update repository index
   apt:
     update_cache: yes
   when: ansible_distribution == "Ubuntu"
 - name: add PHP support for apache
     name: libapache2-mod-php
   when: ansible_distribution == "Ubuntu"
```

If you have a mix of Debian and Ubuntu servers, you can change the configuration of your playbook like this.

 name: update repository index apt:

update cache: yes

when: ansible distribution in ["Debian", "Ubuntu]

Note: This will work also if you try. Notice the changes are highlighted.

4. Edit the *install apache.yml* file and insert the lines shown below.

```
hosts: all
become: true
tasks:

    name: update repository index

  apt:
    update_cache: yes
 when: ansible_distribution == "Ubuntu"

    name: install apache2 package

  apt:
    name: apache2
    stae: latest
 when: ansible_distribution == "Ubuntu"
- name: add PHP support for apache
  apt:
    name: libapache2-mod-php
    state: latest
 when: ansible_distribution == "Ubuntu"
- name: update repository index
 dnf:
    update_cache: yes
 when: ansible_distribution == "CentOS"

    name: install apache2 package

  dnf:
    name: httpd
    state: latest
 when: ansible_distribution == "CentOS"
- name: add PHP support for apache
  dnf:
    name: php
    state: latest
 when: ansible_distribution == "CentOS"
```

Make sure to save and exit.

```

```

5. To verify the installations, go to CentOS VM and type its IP address on the browser. Was it successful? The answer is no. It's because the httpd service or the Apache HTTP server in the CentOS is not yet active. Thus, you need to activate it first.

5.1 To activate, go to the CentOS VM terminal and enter the following: systemctl status httpd

The result of this command tells you that the service is inactive.

5.2 Issue the following command to start the service:

sudo systemctl start httpd

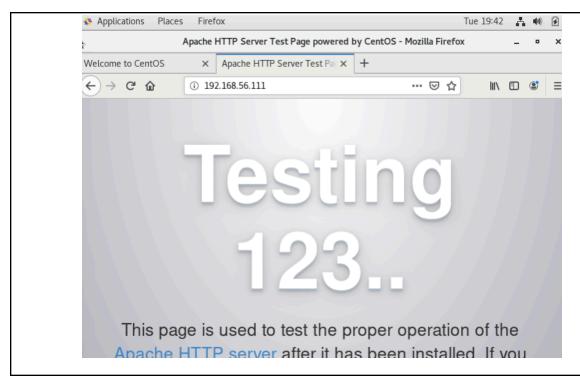

(When prompted, enter the sudo password)

sudo firewall-cmd --add-port=80/tcp

(The result should be a success)

```
[tamayo@localhost ~]$ sudo firewall-cmd --add-port=80/tcp
[sudo] password for tamayo:
success
[tamayo@localhost ~]$
```

5.3 To verify the service is already running, go to CentOS VM and type its IP address on the browser. Was it successful? (Screenshot the browser)

Task 2: Refactoring playbook

This time, we want to make sure that our playbook is efficient and that the codes are easier to read. This will also makes run ansible more quickly if it has to execute fewer tasks to do the same thing.

1. Edit the playbook *install_apache.yml*. Currently, we have three tasks targeting our Ubuntu machines and 3 tasks targeting our CentOS machine. Right now, we try to consolidate some tasks that are typically the same. For example, we can consolidate two plays that install packages. We can do that by creating a list of installation packages as shown below:

```
hosts: all
  become: true
  tasks:
  - name: update repository index Ubuntu
    apt:
      update_cache: yes
    when: ansible_distribution == "Ubuntu"
  - name: install apache2 and php packages for Ubuntu
    apt:
      name:
         - apache2
        - libapache2-mod-php
      state: latest
    when: ansible_distribution == "Ubuntu"
  - name: update repository index for CentOS
    dnf:
      update_cache: yes
    when: ansible_distribution == "CentOS"
  - name: install apache and php packages for CentOS
    dnf:
      name:
        - httpd
        - php
      state: latest
    when: ansible_distribution == "CentOS"
Make sure to save the file and exit.
```

```
install_apache.yml *
 GNU nano 6.2
- hosts: all
 become: true
 - name: install apache2 and php packages for Ubuntu
   apt:
     name:
       - apache2

    libapache2-mod-php

     state: latest
   when: ansible_distribution == "Ubuntu"
 - name: update repository index for Ubuntu
   apt:
     update cache: yes
   when: ansible_distribution == "Ubuntu"
 - name: install apache and php packages for CentOS
   package:
     name:
       - httpd
       - php
     state: latest
   when: ansible_distribution == "CentOS"
 - name: update repository index for CentOS
   package:
     update_cache: yes
   when: ansible_distribution == "CentOS"
```

```
BECOME password:
TASK [install apache2 and php packages for Ubuntu] *****************************
: ok=3 changed=1 unreachable=0 failed=0 skipped=2
escued=0
    ignored=0
        : ok=3 changed=1 unreachable=0 failed=0 skipped=2
escued=0
   ignored=0
        : ok=3 changed=0 unreachable=0 failed=0 skipped=2
escued=0 ignored=0
```

2. Edit the playbook install_apache.yml again. In task 2.1, we consolidated the plays into one play. This time we can actually consolidated everything in just 2 plays. This can be done by removing the update repository play and putting the command update_cache: yes below the command state: latest. See below for reference:

```
hosts: all
become: true
tasks:
 - name: install apache2 and php packages for Ubuntu
    name:
      - apache2
      - libapache2-mod-php
    state: latest
    update cache: yes
   when: ansible_distribution == "Ubuntu"
 - name: install apache and php packages for CentOS
   dnf:
     name:

    httpd

       - php
     state: latest
   when: ansible_distribution == "CentOS"
```

Make sure to save the file and exit.

```
GNU nano 6.2
                                  install apache.yml *
 hosts: all
 become: true
 tasks:

    name: install apache2 and php packages for Ubuntu

   apt:
     name:
        - apache2
        - libapache2-mod-php
     state: latest
     update_cache: yes
   when: ansible_distribution == "Ubuntu"
 - name: install apache and php packages for CentOS
   package:
     name:

    httpd

        - php
     state: latest
        date_cache: yes
GAs_7.0.6
         ansible_distribution == "CentOS"
```

```
BECOME password:
TASK [install apache2 and php packages for Ubuntu] ***********************
skipping: [192.168.56.109]
skipping: [192.168.56.110]
changed=0 unreachable=0
                                failed=0
ipped=1 rescued=0 ignored=0
                                 failed=0
                  changed=0 unreachable=0
     rescued=0 ignored=0
                  changed=0 unreachable=0
                                 failed=0
cipped=1 rescued=0 ignored=0
```

3. Finally, we can consolidate these 2 plays in just 1 play. This can be done by declaring variables that will represent the packages that we want to install. Basically, the apache_package and php_package are variables. The names are arbitrary, which means we can choose different names. We also take out the line when: ansible_distribution. Edit the playbook *install_apache.yml* again and make sure to follow the below image. Make sure to save the file and exit.

```
---
- hosts: all
become: true
tasks:
- name: install apache and php
apt:
    name:
    - "{{ apache_package }}"
    - "{{ php_package }}"
    state: latest
    update_cache: yes
```

Run *ansible-playbook --ask-become-pass install_apache.yml* and describe the result.

4. Unfortunately, task 2.3 was not successful. It's because we need to change something in the inventory file so that the variables we declared will be in place. Edit the *inventory* file and follow the below configuration:

```
192.168.56.120 apache_package=apache2 php_package=libapache2-mod-php
192.168.56.121 apache_package=apache2 php_package=libapache2-mod-php
192.168.56.122 apache_package=httpd php_package=php
```

Make sure to save the *inventory* file and exit.

```
GNU nano 6.2 inventory

192.168.56.109 ansible_python_interpreter=/usr/bin/python3
192.168.56.109 apache_package=apache2 php_package=libapache2-mod-php

192.168.56.110 ansible_python_interpreter=/usr/bin/python3
192.168.56.110 apache_package=apache2 php_package=libapache2-mod-php
```

Finally, we still have one more thing to change in our *install_apache.yml* file. In task 2.3, you may notice that the package is assign as apt, which will not run in CentOS. Replace the *apt* with *package*. Package is a module in ansible that is generic, which is going to use whatever package manager the underlying host or the target server uses. For Ubuntu it will automatically use *apt*, and for CentOS it will automatically use *dnf*. Make sure to save the file and exit. For more details about the ansible package, you may refer to this documentation: ansible.builtin.package — Generic OS package manager — Ansible Documentation

Run ansible-playbook --ask-become-pass install_apache.yml and describe the result.

Supplementary Activity:

1. Create a playbook that could do the previous tasks in Red Hat OS.

Reflections:

Answer the following:

- 1. Why do you think refactoring of playbook codes is important?

 Refactoring playbook code is important because it helps make the code better, easier to understand, and less complicated. This process reduces problems that can build up over time and makes the code run faster and work better as it grows.
- 2. When do we use the "when" command in playbook?

The "when" command in a playbook is used to decide if a task should run based on a specific condition. It's especially helpful when you want to run a task only if certain criteria are met, like the value of a variable or the current status of a system.

CONCLUSION

In this activity, we learned how to customize Ansible playbooks to work with different Linux distributions, like Ubuntu and Debian. By using the "when" command, we can run specific tasks only when certain conditions are met, which helps us manage multiple systems more effectively. We also discussed the importance of keeping our code organized and easy to read by using refactoring techniques. This makes our playbooks simpler and more efficient. Additionally, we highlighted the best practice of using the git pull command to update our local code with any changes made by others. This helps ensure that everyone is working with the latest version of the code, which is especially important in a team environment. In simple terms, these skills help us work better with different systems, keep our code tidy, and stay up-to-date with our team's work.
